1 **Translational Relevance:**

2

3 Cranial meningiomas are heterogeneous. WHO grade using histopathological criteria  
4 falls short in predicting progression free survival in some benign grade I tumors.  
5 Molecular diagnostics have become important in accurately grading other tumors of the  
6 brain, and thus better predicting the natural history. Using proteomic techniques in a  
7 group of genetically-defined clinically aggressive grade I meningiomas (grade 1.5  
8 meningiomas; recurrent, progressive WHO grade I tumors requiring further treatment  
9 within 10 years), RB1 phosphorylation at the S780 site proved to be a biomarker and  
10 mediator of this group. While mutations in NF2, SMO, AKT, KLF4, TRAF7 or wild-type  
11 genotypes did not identify grade 1.5 meningiomas, RB1 phosphorylation at S780 defined  
12 the group. Utilizing a phosphoproteomic approach identified phosphorylation at S780 in  
13 RB1, a long-appreciated tumor suppressor gene. Validation of this biomarker in larger  
14 cohorts from independent medical centers is warranted. Further, additional molecular  
15 study may shed light onto how RB1 S780 is involved with the behavior of clinically  
16 aggressive grade 1.5 meningiomas.

17

1 **Abstract**

2 Purpose: Most WHO Grade I meningiomas carry a favorable prognosis. Some become  
3 clinically aggressive with recurrence, invasion, and resistance to conventional therapies  
4 (grade 1.5; recurrent/progressive WHO grade I tumors requiring further treatment within  
5 10 years). We aimed to identify biomarker signatures in grade 1.5 meningiomas where  
6 histopathology and genetic evaluation has fallen short.

7 Experimental Design: MS-based phosphoproteomics and peptide chip array kinomics  
8 were used to compare grade I and 1.5 tumors. Ingenuity Pathway Analysis (IPA)  
9 identified alterations in signaling pathways with validation by western blot. The selected  
10 biomarker was evaluated in an independent cohort of 140 samples (79/140 genotyped  
11 for meningioma mutations) by tissue microarray and correlated with clinical variables.

12 Results: The MS-based phosphoproteomics revealed differential Ser/Thr  
13 phosphorylation in 32 phosphopeptides. The kinomic profiling by peptide chip array  
14 identified 10 phosphopeptides, including a 360% increase in phosphorylation of RB1, in  
15 the 1.5 group. IPA of the combined datasets and western blot validation revealed  
16 regulation of AKT and Cell Cycle Checkpoint cascades. Rb1 hyperphosphorylation at the  
17 S780 site distinguished grade 1.5 meningiomas in an independent cohort of 140  
18 samples and was associated with decreased progression/recurrence-free survival.  
19 Mutations in *NF2*, *TRAF7*, *SMO*, *KLF4*, and *AKT1* E17K did not predict RB1 S780  
20 staining or progression in grade 1.5 meningiomas.

21 Conclusions: Rb1 S780 staining distinguishes grade 1.5 meningiomas, independent of  
22 histology, subtype, WHO grade or genotype. This promising biomarker for risk  
23 stratification of histologically bland WHO grade I meningiomas provides insight into the  
24 pathways of oncogenesis driving these outlying clinically aggressive tumors.

25

26

## 1 **Introduction**

2 Meningiomas account for one-fourth of all primary brain neoplasms (1). The  
3 World Health Organization (WHO) provides a link between histopathology and risk of  
4 progression/recurrence by classifying meningiomas as grade I (benign), grade II  
5 (atypical, clear cell and chordoid subtypes), or grade III (anaplastic) (2). There are 9  
6 different histological subtypes of WHO I, with the majority cured by surgery. Some WHO  
7 grade I tumors metastasize (3), rapidly grow (4), invade brain, blood vessels and cranial  
8 nerves (5). Benign meningiomas can reoccur after gross total resection (6) with rapid  
9 progression (7). Radiation or radiosurgery are reserved for when surgery is no longer an  
10 option, although some tumors prove refractory (8). These observations support the  
11 concept of a group of histologically benign meningiomas, which unexpectedly behave  
12 clinically aggressive.

13 WHO I meningiomas lack atypical or anaplastic features, and are managed as  
14 benign tumors. Brain invasion is enough to upgrade otherwise bland tumors to grade II  
15 (atypical), but is dependent on capturing brain tissue on the pathology section. These  
16 tumors have higher rates of recurrence, progression and altered mortality rates (9).  
17 Identification of these tumors is imperative for treatment.

18 Molecular markers are needed to identify clinically aggressive grade I  
19 meningiomas (grade 1.5 meningiomas; recurrent, progressive WHO grade I tumors  
20 requiring further treatment within 10 years (10)), where histology falls short. The grade  
21 1.5 meningioma follows a more clinically aggressive natural history as compared to its  
22 WHO grade I counterpart. Deletion of 1p and/or 14q is thought to predict recurrence and  
23 progression, correlating with tumor grade (6, 11). Recent studies show that benign  
24 tumors with similar alterations in their genome can become clinically aggressive and  
25 reoccur (12). These results have not translated into biomarkers for diagnosis, risk  
26 stratification nor offer chemotherapeutic targets. Recently, methylation status was shown  
27 to segregate WHO I tumors, and lower risk WHO II meningiomas (13), suggesting that  
28 epigenetics may play a larger role.

29 Pathways in cancer cells lead to increased proliferation, differentiation, migration,  
30 and survival. Post-translational modifications include phosphorylation by kinases.  
31 Advances in proteomic techniques have led to a new understanding of the  
32 phosphoproteome in human tissue (14) and cell lines (15). Peptide arrays (16), reverse-  
33 phase protein arrays (17), antibody arrays (18) and mass spectrometry (MS; 16) have  
34 been used to characterize cancer. Phosphoproteomics have resulted in advances in

1 oncology; phosphorylation of oncoproteins in their native environment, molecular  
2 mechanisms that drive tumorigenesis (17), radio-resistance (19), cellular networks of  
3 drug response (20). From these data, pharmacological targets have led to the  
4 development of kinase inhibitors.

5         Few studies have investigated the proteome of benign meningiomas (21, 22).  
6 Most of them lack clinical information and compare different grades. Our group used  
7 phosphoproteomics to establish signatures of histologically well-defined WHO grade I-III  
8 meningiomas (16). Using low-resolution 2D gel followed by MS identification we also  
9 described unique proteins in clinically aggressive WHO I meningiomas (10). Utilizing  
10 higher-resolution phosphoproteomics we aimed to further characterize grade 1.5  
11 meningiomas for risk stratification and evaluation of patterns of oncogenesis.

12

13

14

1 **Methods**

2 **Tissue specimens, patients and clinical data**

3 Studies were conducted in accordance with U.S. Common Rule ethical guidelines. Data  
4 and specimen collection were reviewed and approved by the University of Washington  
5 Institutional Review Board and Human Subjects Division. Written informed consent was  
6 obtained from all subjects. Methods were carried out in accordance with relevant  
7 guidelines and regulations. Patients underwent surgery at the University of Washington  
8 Hospitals between January 1<sup>st</sup> 1998 and December 31<sup>st</sup> 2012. Samples were collected  
9 and stored in -80°C. Data was gathered regarding history, demographics, imaging,  
10 neuropathology reports, operative information, and outcomes. Resected tumors were re-  
11 graded according to revised criteria (2). Histological subtype, mitoses, Ki-67/MIB,  
12 sheeting, macronuclei, hypercellularity, and necrosis were recorded. Invasion was  
13 recorded from operative or pathology reads. Specimens were reviewed by three  
14 neuropathologists and neurosurgeons. Total resection was defined as absence of  
15 residual enhancement on post-operative MRI within 48 hours of surgery. Recurrence  
16 was defined as at least 1cm of enhancement on subsequent MRI. Progression was  
17 considered to be at least 1cm of growth of residual tumor on MRI after surgery. Patients  
18 were initially divided according to tumor grade (WHO I, II and III). Benign meningiomas  
19 were grouped into: clinically “non-aggressive” WHO grade I meningioma, designated as  
20 WHO I and clinically “aggressive” WHO grade I meningioma designated as grade 1.5.  
21 WHO I meningiomas underwent complete resection, with no evidence of  
22 progression/recurrence on imaging at a follow-up period of 120 months. Grade 1.5  
23 included: 1) Patients undergoing gross resection for a WHO I meningioma requiring  
24 repeated resection for recurrence within 120 months (second surgery confirming WHO  
25 I), 2) Patients undergoing gross resection of a WHO I meningioma and requiring  
26 Stereotactic Radiosurgery (SRS) for a recurrence within 120 months, and demonstrating  
27 progression despite SRS. 3) Patients undergoing more than two operations for a  
28 recurrent WHO I tumor. The discovery set included five individual meningioma fresh-  
29 frozen tissue samples classified as WHO I, and five classified as grade 1.5. Clinical and  
30 histological features of the discovery set are described in Supplementary Table S1 and  
31 Table S2, respectively. The Cohort 01 tissue microarray (TMA) included 81 meningioma  
32 samples (31 grade I, 19 grade 1.5, 27 grade II, and 4 grade III) (Supplementary Table  
33 S3). Five samples (sample ID 2, sample ID 24, sample ID 46, sample ID 51, and sample  
34 ID 76) were excluded from the analysis due to tissue loss during sectioning, transfer, or

1 staining. The values of staining obtained for the sample ID 13 and 14 were averaged  
2 since they are from the same patient and resected at same surgery. Cohort 02 included  
3 target resequencing of *NF2*, *TRAF7*, *SMO*, *KLF4*, and *AKT1* E17K of 20 tumors (from  
4 Cohort 01, Supplementary Table S3). Target resequencing was performed in 59  
5 additional cases in Cohort 03, and stained for RB1 S780 in this TMA (Supplementary  
6 Table S4).

7

### 8 **Targeted resequencing with Molecular Inversion Probes (MIP)**

9 DNA was extracted using QIAamp DNA Mini Kit (Qiagen, Valencia, CA) following  
10 quantification on Qubit (Life Technologies, Foster City, CA, USA). Probes were  
11 synthesized by Integrated DNA Technologies, Inc. (Redwood City, CA), pooled and  
12 phosphorylated. Sequencing and analysis were performed as described (16). Reads  
13 were mapped to GRCh37 using BWA-MEM after the MIP targeting sequence was hard  
14 clipped from the read. Indel realignment and base quality recalibration was performed  
15 according to GATK Best Practice's documentation. Variants were called using GATK's  
16 HaplotypeCaller in gvcf format and subsequently jointly called using GATK's  
17 GenotypeGVCF. A cut-off allele frequency > 4% was applied.

18

### 19 **iTRAQ labeling and phosphopeptide enrichment**

20 We utilized techniques similar to our prior work (16). Briefly, proteins were extracted  
21 from fresh-frozen meningioma specimens with T-PER Buffer (Thermo Scientific Pierce,  
22 Pittsburgh, PA) supplemented with 1:100 Phosphatase Inhibitor Cocktail and 1:100 Halt  
23 Protease Inhibitor Cocktail EDTA free (Thermo Scientific Pierce, Pittsburgh, PA). Protein  
24 lysates were quantified by Quibit. For the Isobaric Tags for Relative and Absolute  
25 Quantitation (iTRAQ)-based quantitative phosphoproteomic experiment, equal amounts  
26 of protein from five non-irradiated individual samples of WHO I and five non-irradiated  
27 individual samples from grade 1.5 meningioma were pooled to create two pools. Pooled  
28 lysates were precipitated, digested, labeled with tags (Life Technologies, Grand Island,  
29 NY); WHO I – iTRAQ114, and grade 1.5 – iTRAQ115, combined, and desalted.  
30 Phosphopeptides were allowed to bind to TiO<sub>2</sub> spin tips using Phosphopeptide  
31 Enrichment and Clean-up Kit (Thermo Scientific Pierce, Pittsburgh, PA), eluted, and  
32 cleaned using graphite columns (Thermo Scientific Pierce, Pittsburgh, PA). Samples  
33 were dried and resuspended in TFA. LC MS/MS analysis was performed as described  
34 previously (16). The spotted sample plates were analyzed using 4800 Plus MALDI

1 TOF/TOF TM (AB SCIEX, Framingham, MA) with mass range of 800–3500 m/z and S/N  
2 >50. MS/MS spectral data were analyzed using ProteinPilot 4.0 (AB SCIEX,  
3 Framingham, MA) referencing International Protein Index (IPI) and UniProtKB/Swiss-  
4 Prot database using Proteome Discoverer 1.3 (Thermo Scientific, Pittsburgh, PA) with  
5 the parameters: MMTS for cysteine alkylation, up to two trypsin missed cleavages;  
6 biological modification, amino acid and substitutions were set for ID focus;  
7 phosphorylation emphasis, FDR <5%, and confidence >95%. Data were normalized, and  
8 quantification expressed as ratio with WHO I levels (iTRAQ 114) as the denominator. A  
9 protein was considered differentially expressed when the iTRAQ ratio (grade 1.5:WHO I)  
10 was >1.20 or <0.83, or a fold change >20%. The fold-change cutoff for up- or down-  
11 regulation was determined based on pilot studies evaluating the label-specific  
12 experimental variation between two replicates for the same experimental group. Similar  
13 approaches have been employed by our group (16, 23, 24, 25) and others (26, 27) to  
14 identify relevant candidates in iTRAQ studies.

15

#### 16 **Serine/threonine kinase (STK) profiling**

17 The PamStation®12 and STK PamChip® peptide array (PamGene International BV,  
18 Hertogenbosch, Netherlands) were used (16). The fluorescent platform measures the  
19 ability of active kinases in a specimen to phosphorylate specific peptides imprinted on  
20 multiplex chip arrays. Each chip contains 4 arrays. Each array displays 140 Ser/Thr and  
21 4 positive control immobilized peptides. Each peptide represents a 15 amino-acid  
22 sequence from putative phosphorylation sites in human proteins derived from the  
23 literature and correlated with one or multiple upstream kinases. Kinase(s) in the sample  
24 actively phosphorylate substrates on the PamChip®, in the presence of ATP. An  
25 antibody is used to detect phosphorylation, and a 2<sup>nd</sup> FITC-conjugated antibody is used  
26 to quantify the signal. Three temperature-controlled peptide chips ran in parallel. Chips  
27 were blocked with 2% BSA (Sigma-aldrich, St. Louis, MO). Proteins were extracted from  
28 fresh-frozen meningiomas with T-PER Buffer (Thermo Scientific Pierce, Pittsburgh, PA)  
29 supplemented with 1:100 Phosphatase Inhibitor Cocktail and 1:100 Halt Protease  
30 Inhibitor Cocktail EDTA free (Thermo Scientific Pierce, Pittsburgh, PA). Protein lysates  
31 were quantified by Quibit. Equal amounts of protein from five non-irradiated individual  
32 samples of WHO I and five non-irradiated individual samples from grade 1.5  
33 meningiomas were pooled to create two pools (WHO I and 1.5). 1 µg of protein from  
34 each pool was applied to individual arrays with kinase buffer, 400 µM ATP, and FITC-

1 conjugated antibodies. Signal intensities were quantitated by BioNavigator 6.1.42  
2 (PamGene), expressed per 100 ms exposure and log transformed. Mean value <20% for  
3 peptides with a signal >2000 was considered to ensure quality standards. Normalization  
4 was applied. Three replicated quantitations were combined using FDR <1%. A p-value  
5 <0.05 and a >10% fold change, were considered significant.

### 6 7 **Western blot analysis**

8 Three WHO I (1174, 1289, 1149) and three grade 1.5 samples (1432, 1494, 1893),  
9 which were part of our discovery set (Table S1, and S2), were submitted to western blot  
10 for validation. The other samples (WHO I: 1480, 6, and grade 1.5: 2002, 1379) were not  
11 included as these tissues were exhausted in performing MIP, iTRAQ mass spectrometry,  
12 and STK profiling. Proteins were extracted from meningioma fresh-frozen tissue with T-  
13 PER Buffer (Thermo Scientific Pierce, Pittsburgh, PA) supplemented with 1:100  
14 Phosphatase Inhibitor Cocktail and 1:100 Halt Protease Inhibitor Cocktail EDTA free  
15 (Thermo Scientific Pierce, Pittsburgh, PA). Proteins were quantified using Quibit. 20ug of  
16 protein extract was combined with reducing Laemmli buffer, boiled for 5 min and then  
17 resolved by polyacrylamide gels. Polyacrylamide gels were transferred to PVDF  
18 membranes, incubated with primary antibody, overnight, and then with HRP-conjugated  
19 secondary antibody. Membranes were developed with Clarity Western ECL Substrate  
20 (Bio-rad, Hercules, CA) and visualized in GelDoc XR+ System (Bio-rad, Hercules, CA).  
21 For loading control, membranes were stripped and re-probed with anti- $\beta$ -actin. Band  
22 intensity was quantified using Image Studio Lite Version 5.0 (LI-COR Biosciences,  
23 Lincoln, NE). Relative band densitometry is presented as mean  $\pm$  SEM of the three  
24 samples of each meningioma grade. Antibodies are listed in Supplementary Table S5.

### 25 26 **Tissue Microarray (TMA)**

27 Samples were fixed in formalin, processed in tissue processor, and embedded in  
28 paraffin to produce FFPE blocks. Regions suitable for TMA were selected in duplicate. A  
29 blinded scientist created a randomized tissue microarray. All TMA slides for cohorts 01  
30 and 03 were sectioned producing 4 $\mu$ m sections, placed on slides, and stained with H&E.  
31 Antibody optimization was performed using Leica Bond III Fully Automated IHC and ISH  
32 Staining System (Leica Bio-Systems, Buffalo Grove, IL). Anti-phospho-Rb1 S780 was  
33 used. The final step included the Bond Polymer Define Detection System (Leica Bio-  
34 Systems, Buffalo Grove, IL), containing endogenous peroxidase blocking, secondary

1 antibody, and a streptavidin–biotin detection system. Slides were counterstained with  
2 Gill's Hematoxylin. Controls were included with antibody run. The slides were scanned  
3 using NanoZoomer Digital Pathology System (Hamamatsu Photonics, K. K., San Jose,  
4 CA). Images were analyzed by Visiopharm (Hoersholm, Denmark) which converted the  
5 initial digital imaging into grayscale values using HDAB – DAB with the Chromaticity Red  
6 feature subtracted, an H&E with filter of 3X3 pixels, and an RGB - G feature. Analyses  
7 were conducted in a blinded fashion. Quantification of Rb1 was performed by automated  
8 image analysis of regions of interest. The ratio of Rb1 S780 per total tissue area was  
9 determined. The patterns of staining were divided into quartile groups (0, low, medium  
10 and high) and only the highest group used as high. The most stringent of criteria for  
11 labeling Rb1 as high was used and this objective cutoff was 0.088. Rb1 staining was  
12 considered low when ratio < 0.088 and considered high when ratio > 0.088.

13

#### 14 **Bioinformatics tools**

15 Computational prediction of kinase phosphorylation was performed by GPS 2.1 (28) and  
16 PhosphoNet Kinexus ([www.phosphonet.ca](http://www.phosphonet.ca)). Kinome trees were annotated using Kinome  
17 Render (29). Prediction of phosphorylation consensus motifs was performed by NetPhos  
18 server (30). IPA (Ingenuity Systems, Redwood City, CA) was used to identify  
19 mechanisms, functions, and predict upstream regulators. See reference 16.

20

#### 21 **Statistics**

22 Comparison of the levels of the peptides/proteins in meningioma groups was performed  
23 using the nonparametric Mann-Whitney test and Kruskal-Wallis, when appropriate.  
24 Statistical significance of Rb1 S780 phosphorylation by grade was analyzed by mixed-  
25 effects regression using grade ranks to test for an ordinal relationship. Correlation  
26 between Rb1 S780 phosphorylation and clinical variables was assessed by Spearman  
27 and Kruskal-Wallis, as appropriate. Mutation prevalence by meningioma grade were  
28 evaluated using exact logistic regression. Analyses were adjusted for multiple  
29 comparisons using Holm-Bonferroni when appropriate. Time-to-recurrence was  
30 evaluated using log-rank tests and Cox regression. For the statistical analyses of band  
31 densitometry for Western Blotting, the data is presented as mean  $\pm$  SEM of the three  
32 samples of each meningioma grade (P-values were calculated using both Student's t  
33 test and nonparametric testing. All differences were significant when  $p < 0.05$ .

3 request.

4

## 5 **Results**

### 6 **MS-based phosphoproteomic profiling of meningioma grade 1.5.**

7 While alterations in *SMO*, *KLF4*, *TRAF7*, *NF2*, and *AKT E17K* have been found in  
8 meningiomas, the downstream protein signature underlying clinically aggressive WHO  
9 grade I meningiomas is unknown. In an attempt to understand protein specific alterations  
10 underlying a clinically aggressive phenotype of WHO grade I meningioma we utilized  
11 proteomic profiling. Phosphorylation and kinase activity could lead to novel mechanistic  
12 insight and potential biomarker identification and thus iTRAQ phosphopeptide  
13 enrichment followed by quantitative mass spectrometry analysis of the ten meningioma  
14 specimens (discovery set, Supplementary Table S1 and S2) was performed. WHO  
15 grade I and grade 1.5 pools were labeled iTRAQ114 and iTRAQ115, respectively,  
16 following mass spectrometry analysis (Supplementary Figure S1a). A total of 649 unique  
17 phosphopeptides corresponding to 165 proteins were identified (Supplementary Table  
18 S6). From the 649 candidates, we selected 32 unique phosphopeptides with an  
19 individual composite score of  $\geq 95\%$  confidence, top-ranked matching sequence for that  
20 spectrum, and iTRAQ ratios from meningioma grade 1.5 compared to benign WHO I  
21 tissue greater than 1.20 or less than 0.83 (fold change  $> 20\%$ ) at a FDR  $< 5\%$   
22 (Supplementary Figure S1b). Fifteen proteins (46.9%,  $n=15/32$ ) showed  
23 hyperphosphorylation at Ser/Thr residues, among them the ABCF1, ABLIM1, ADD1,  
24 AKAP12, CTTN, PBDC1, DBNL, EIF4B, GLCE, HNRNPD, HSPB1, LMNA, Septin-2,  
25 VCAN, and VCL. Seventeen proteins (53.1%,  $n=17/32$ ) showed hypophosphorylation at  
26 serine or threonine residues, including; ADD3, CANX, DPYSL3, EML4, EPB41L2,  
27 G3BP1, HSP90AB1, MAP1B, MARCKS, PGRMC1, PLEC, PPP1R2, SDC2, SEC22B,  
28 TGOLN2, TP53I1, and VIM. Western blot validation of the iTRAQ analysis was  
29 performed (Supplementary Figure S1c). Phosphoproteins for western blot validation  
30 were selected according to antibody commercial availability. The levels of  
31 phosphorylation or protein expression were analyzed in three individual fresh frozen  
32 tissue specimens of each meningioma grade, which were also part of the discovery set.  
33 We observed that phosphorylation of DPYSL3 S522 ( $p = 0.003$ ), G3BP1 S232 ( $p =$

1 0.004), and CANX S583 ( $p = 0.006$ ) correlated with the phosphoproteome dataset  
2 (Supplementary Figure S1c, Supplementary Figure S2).

3 We used IPA to explore alterations in phosphorylation of 32 phosphoproteins  
4 (Supplementary Figures S3 and S4). PKC, cAMP/PKA, PI3K-MTOR-AKT, MAPK-ERK,  
5 and RHO GTPases are common themes in these cascades. The MKNK1 and mTOR  
6 were predicted as upstream regulators of the cascade (Supplementary Figure S4b).

7

### 8 **Serine-Threonine kinome profiling of grade 1.5 meningiomas**

9 We performed kinome profiling of WHO grade I and grade 1.5 meningiomas. Pooled  
10 lysates from fresh-frozen specimens were characterized using PamChip® peptide array  
11 Ser/Thr kinase platform (STK). The experimental workflow is shown in Figure 1a. Only  
12 peptides above the limit of detection were included ( $n=101/140$ ) (Supplementary Table  
13 S7). The 2Log transformed signal intensities of the 101 peptides above limit of detection  
14 were clustered and represented as a heat map (Figure 1b, Supplementary Table S7).  
15 Fold change analysis of grade 1.5 versus WHO I meningiomas showed 10/101 peptides  
16 with significantly increased phosphorylation changes, among them RB\_774\_786. Rb1  
17 demonstrated over a 360% increase in phosphorylation levels in the more clinically  
18 aggressive, 1.5 group (Figure 1c). This phospho-peptide contains three phospho-sites  
19 (T774, T778, and S780). Further, analysis of the phosphorylation consensus motif  
20 indicates that S780 in the motif T-R-P-P-T-L-S-P-I-P-H-I-P of Rb1 is the predicted  
21 phosphorylation site. This is a consensus site for CDKs kinases (Supplementary Figure  
22 S5c). Downstream activation of related signaling pathways (Figure 1d) was predicted in  
23 this group of tumors.

24

### 25 **Combined analysis of the iTRAQ/MS-based global phosphoproteome and kinome** 26 **for interpretation of signaling networks in grade 1.5 meningiomas.**

27 We combined datasets (significantly altered 32 phosphopeptides in the iTRAQ and 10  
28 proteins from the STK chip) to perform computational analysis, to gain insight into the  
29 mechanisms of grade 1.5 meningiomas. First, we utilized computational prediction of  
30 phosphorylation sites by their cognate Ser/Thr kinases. The analysis predicted 85  
31 potential upstream kinase regulators mainly included in the AGC and CMGC groups  
32 (Supplementary Figure S3a). CDKs, CDC42, and MAPKs are three of the largest CMGC  
33 groups and mediate the function of a variety of tumor suppressors in the ERK-MAPK  
34 transduction pathway (32). The AGC group includes AKT, PKA, PKG, and PKC protein

1 kinases (33). The IPA analysis predicted mTOR as a regulator of grade 1.5  
2 meningiomas (Supplementary Table S8, mTOR highlighted in yellow) and showed a  
3 direct relationship with hyperphosphorylated Rb1 as well as with FRAP1-Hd, SEC22B,  
4 HSPB1, G3BP1, SEPT2, PGRMC1, and HSP90AB1 (Supplementary Figure S5b). The  
5 Rb1 S780 site is a consensus site for CDKs kinases. Taken together, the computational  
6 analyses suggest that PI3K-AKT-mTOR, ERK-MAPK, PKA, CDC42-RAC1-RHOA, and  
7 Rb1/E2F signaling pathways may be altered in grade 1.5 meningiomas.

8

### 9 **Canonical pathways and upstream kinases validation by Western Blotting**

10 Western blot analysis of PI3K-AKT-MTOR, ERK-MAPK, PKA, CDC42-RAC1-RHOA, and  
11 Rb1/E2F signaling pathways (Figure 2 and Supplementary Figure S7) was performed.  
12 Significant decreases in AKT S473, AKT T308 and downstream targets IKK $\alpha$  T23, and  
13 RAF1 were found (PI3K-AKT-MTOR) (Figure 2a and Supplementary Figure S7a). In the  
14 ERK-MAPK pathway, the increased expression of p38 MAPK distinguishes the 1.5  
15 group (Figure 2b and Supplementary Figure S7b). Phosphorylated cAMP/PKA targets,  
16 CAMKII and PKAC were seen (Figure 2c). Proteins intimately involved with the CDC42-  
17 RAC1-RHOA pathway played a smaller role and were not significantly altered in the  
18 grade 1.5 group of tumors (Figure 2d). Significantly increased levels of CDK4, CDK6 and  
19 Rb1 S780 were seen (Figure 2e and Supplementary Figure S7e), together implying a  
20 defining signature of cell cycle G1/S checkpoint signaling in grade 1.5 meningiomas.  
21 Figure 2f is a table illustrating significantly altered proteins and respective p values.

22

### 23 **Hyperphosphorylation of Rb1 S780 predicts recurrence in WHO I meningiomas,** 24 **identifying the 1.5 subgroup.**

25 We used TMA methods to explore whether Rb1 S780 staining was found in  
26 meningiomas of varying grades, specifically grade 1.5 tumors. Rb1 S780 staining was  
27 analyzed in multiple TMA cohorts (Supplementary Table S9) which included samples  
28 prior to and after radiation treatment (Supplementary Table S10). The levels of Rb1  
29 S780 staining were quantified (Supplementary Figure S8). Meningioma specimens with  
30 no prior radiation treatment (107 total tumors; 47 grade I, 28 grade 1.5, 31 grade II, and  
31 1 grade III) and specimens with prior radiation treatment (33 total tumors; 0 grade I, 16  
32 grade 1.5, 14 grade II, and 3 grade III) (Supplementary Table S3 and S4) were included.  
33 We performed univariate and multivariate analyses of Rb1 S780 phosphorylation to  
34 evaluate the ability to distinguish 1.5 tumors (Supplementary Table S11 and Table 3a).

1 Potential confounders revealed by the univariate analysis (Supplementary Table S11)  
2 were considered in the multivariate model (Table 1a). Rb1 S780 phosphorylation  
3 distinguishes 1.5 tumors. Rb1 S780 phosphorylation by grade is statistically significant  
4 and it is increased in grade 1.5 tumors in all samples (Figure 3c) as well as in samples  
5 with no prior radiation treatment (Figure 3d, Table 1a). Irradiated samples did not show  
6 differences in Rb1 S780 phosphorylation (Figure 3e, Table 1a). It is noteworthy that the  
7 discovery set of tumors were non-irradiated samples.

8 Kaplan Meier and Cox analyses of Rb1 S780 phosphorylation versus  
9 progression/recurrence-free survival were performed to identify its potential prognostic  
10 value. In all samples, independent of WHO grade, Rb1 S780 phosphorylation is  
11 associated with lower progression/recurrence-free survival ( $p = 0.004$ , Figure 3f, Table  
12 1b). In non-irradiated samples ( $p = 0.0001$ ) (Figure 3g, Table 1b) increased Rb1 S780  
13 staining was also associated with decreased progression/recurrence-free survival. This  
14 was not visualized in the sample cohort with prior radiation treatment (Figure 3h, Table  
15 1b).

16 Within the histologically benign samples, grade 1.5 meningiomas, had higher  
17 levels of phosphorylation of Rb1 at S780. Prior radiation tended to correlate with  
18 decreased phosphorylated Rb1 across groups (Figure 3e). Considering that radiation  
19 may change the characteristics of a tumor and only non-irradiated samples were present  
20 in the discovery set, we focused on the significance of progression/recurrence-free  
21 survival versus Rb1 S780 staining in samples without previous radiation, by grade.  
22 Phosphorylation of Rb1 at S780 in non-irradiated, histologically benign, tumors  
23 correlated with progression/recurrence-free survival (Figure 3j, Table 1b). This  
24 correlation was not seen in this group when radiation was given prior to the surgery  
25 (Figure 3k).

26 To better understand the role that Rb1 S780 staining plays in temporal  
27 aggressiveness of the grade 1.5 group of tumors we separated these tumors based on  
28 the timing of the sample collection. That is, whether the sample was obtained at the first  
29 operation versus the 2<sup>nd</sup>-5<sup>th</sup> surgery in the patient's course of treatment. There were 140  
30 meningiomas stained for Rb1 S780 (of which 79 underwent MIP resequencing). This  
31 included 47 grade I tumors and 28 grade 1.5 tumors with no radiation history. Of the 28  
32 grade 1.5 meningiomas, 16 were obtained from the 1<sup>st</sup> operation and 12 from the 2<sup>nd</sup>-5<sup>th</sup>  
33 operation. To address whether RB1 S780 staining occurs prior to the recurrence or  
34 progression, we have separated out the samples obtained at the 1<sup>st</sup> and subsequent

1 (2<sup>nd</sup>-5<sup>th</sup>) operations, for clarity (see Supplementary Tables S9 and S10). The Figure 3l  
2 shows a KM curve comparing three groups (without prior radiation): grade I, grade 1.5 at  
3 1<sup>st</sup> operation and grade 1.5 at 2<sup>nd</sup>-5<sup>th</sup> operation. Phosphorylated RB1 S780, identifies the  
4 grade 1.5 group regardless of timing of tissue collection (Figure 3l). The difference in  
5 progression free survival, between grade 1.5 groups (1<sup>st</sup> vs. subsequent operations),  
6 was not significant ( $p=0.236$ ). To further illustrate the specificity of phosphorylated Rb1  
7 S780 for the grade 1.5 group of tumors, an analysis was undertaken in grade 2 and 3  
8 meningiomas. Rb1 S780 staining in histologically aggressive meningiomas (grade II +  
9 III), without prior radiation, did not correlate with progression/recurrence-free survival  
10 (Figure 3m). Rb1 staining at the S780 site is a unique, specific and robust marker for  
11 grade 1.5 meningiomas and may highlight a pathway that can be exploited for therapies.  
12

### 13 **Screening of the *SMO*, *KLF4*, *TRAF7*, *NF2*, and *AKT* E17K mutations by MIP and** 14 **relationship with RB1 S780 staining.**

15 Recurrent mutations in *SMO*, *KLF4*, *TRAF7*, *NF2*, and *AKT* genes (31), could  
16 potentially underlie the pathogenesis of grade 1.5 meningiomas. We sought to explore  
17 the relationship between alterations in these genes and both RB1 S780 staining and  
18 recurrence/progression free survival. Target resequencing of *NF2*, *TRAF7*, *SMO*, *KLF4*,  
19 and *AKT1* E17K was performed in an additional cohort of 79 tumors (26 grade I, 25  
20 grade 1.5, 26 grade II and 2 grade III) with both MIP genotyping and RB1 S780 staining.  
21 The Tables 2a and 2b show the analyses for testing a relationship between WHO grade  
22 and presence of mutation for each of 6 genetic factors, as well as RB1 S780 staining,  
23 respectively. Exact logistic regression was used in order to avoid the pitfalls of low cell  
24 counts, thus correlated effects due to repeated subjects were ignored. The only mutation  
25 showing a significant relationship with grade is *TRAF7*, which remained statistically  
26 significant ( $p=.020$ ) after adjusting for the experiment-wise error due to multiple  
27 comparisons (Holm-Bonferroni,  $m=6$ ). However, the strength of this relationship appears  
28 to be driven mainly by the high prevalence in Grade I as compared to Grades 1.5/II/III.  
29 There are no discernable differences in prevalence or odds-ratios among the higher  
30 grades, thus inferring a monotonic relationship among the higher grades is not  
31 necessarily warranted. Mutations in *SMO* initially showed significance on its own, but the  
32 effect (which was in the opposite direction of *TRAF7*) washed away after adjusting for  
33 multiple comparisons ( $p=.108$ ). High RB1 was highly related to grade in the mutation  
34 ( $N=79$ ,  $p=.008$ ) and non-radiated ( $N=107$ ,  $p=.013$ ) samples, but less so in the full

1 (N=140, p=.059) sample. However, note that the relationship is decidedly not  
2 monotonic, as contrary to the mutation analyses the odds ratios decrease within just the  
3 higher grades (1.5/II/III). For this reason, the relationship would be better characterized  
4 with grade as dichotomous (i.e. I vs 1.5/II/III). RB1 S780 staining was most reliable in  
5 identifying the grade 1.5 meningiomas, in this group.

6 We next aimed to test for a relationship between recurrence/progression time  
7 and presence of mutation for each of 6 genetic factors. The Supplementary Table S12  
8 summarizes the difference between each of the "no-mutation" and "mutation" survival  
9 curves (log-rank test), and also provides estimates of hazard ratios and mean time to  
10 recurrence (Cox proportional-hazards regression). Presence of the TRAF7 mutation  
11 was associated with lower risk for recurrence/progression (Hazard Ratio = 0.18, 95% CI  
12 = 0.04, 0.77, p=.009), even after adjustment for multiple comparisons (p=.044).  
13 Presence of the KLF4 mutation was associated with higher risk for  
14 recurrence/progression (Hazard Ratio = 9.65, 95% CI = 2.12, 43.9, p<.001), even after  
15 adjustment for multiple comparisons (p=.002). The KLF4 and SMO hazard-ratio  
16 estimates should be considered unreliable due to the low prevalence of mutation. While  
17 TRAF7 and KLF4 mutations may correlate with decreased and increased risk of  
18 recurrence/progression, respectively, neither alteration identified the grade 1.5  
19 meningiomas. RB1 S780 staining was most reliable in identifying the grade 1.5  
20 meningiomas with a decrease in progression free survival.

## 1 Discussion

2 Meningiomas are a heterogeneous group of tumors, characterized by WHO  
3 grading. Up to 20% of benign meningiomas reoccur even after gross resection (6) and  
4 progression of residual disease can be rapid (7). Radiation or radiosurgery are usually  
5 reserved for when surgery is not an option, although some tumors prove refractory to  
6 this treatment (8). These observations support the concept of a group of histologically  
7 benign meningiomas, which clinically behave more aggressively. Identifying these  
8 outliers is imperative for treatment planning and surveillance, prior to clinical  
9 aggressiveness. When WHO I meningiomas invade brain, they are automatically  
10 upgraded to WHO II (2). This diagnosis is dependent on the presence of brain tissue in  
11 the histological specimen, bringing up the possibility of WHO I tumors being under  
12 graded because of the lack of brain tissue in the specimen. Since these tumors follow a  
13 different natural history and recurrence pattern, it is imperative to identify them. These  
14 tumors have similar MIB, ki67 and histology patterns (4). Improved biomarkers for  
15 identification of these outlying tumors would aid in better classifying for adjuvant  
16 planning.

17 Numerous studies have focused on DNA alterations in aggressive meningiomas  
18 (35, 36). Chromosomal gains and losses (37), (e.g. monosomy 22) or specific genotypes  
19 (e.g. *NF2* mutations) and next-generation sequencing (31), are promising. The majority  
20 of WHO grade I meningiomas (50%–60%) are linked to *NF2* mutations. We performed  
21 target resequencing of *NF2*, *TRAF7*, *SMO*, *KLF4*, and *AKT1* E17K in an additional  
22 cohort of meningioma samples, including the discovery set samples (Supplementary  
23 Table S3 and S4). The Table 2a shows the analysis testing for a relationship between  
24 grade and presence of mutation for each of 6 genetic factors (5 gene mutations and  
25 Wild-type). We did not find a correlation between alterations in *SMO*, *KLF4*, *TRAF7*,  
26 *NF2*, and *AKT* E17K mutations with WHO grade or clinical aggressiveness of grade 1.5  
27 tumors. There was a trend of *TRAF7* mutations and more benign natural history. Further,  
28 there was a trend of *KLF4* mutations and a more rapid recurrence/progression natural  
29 history. While these results must be confirmed in a much larger cohort of samples with  
30 excellent clinical outcome data, it is even more impressive that Rb1 S780 staining  
31 performed well in identifying grade 1.5 tumors in this group of samples.

32 Gene expression profiling focused on tumor grade specific transcription has been  
33 useful for showing unique profiles. A recent study shed light onto several meningioma  
34 subgroups, defined by genome methylation status, including an aggressive subgroup of

1 WHO grade I tumors (13). Utilizing 2D gel electrophoresis and MS, our group detected a  
2 unique group of proteins that distinguished clinically aggressive grade I tumors (10).  
3 Focusing on phosphorylation events, AKAP12 was also associated with meningioma  
4 progression (16). Proteomic studies can add to the increasing volume of genetic and  
5 transcriptional studies, toward a goal of better biomarkers for meningioma patients.  
6 These data provide proof of this concept.

7 In the classification of gliomas, the use of FISH for detection of 1p/19q loss in  
8 oligodendrogliomas directs therapy and predicts natural history (38). Further, MGMT  
9 hypermethylation and IDH1 mutation status help with prognosticating in high-grade  
10 gliomas (39). These examples provide real time biomarkers shedding light onto the  
11 pathogenesis of a solid brain tumor, where WHO grading is insufficient.

12 Protein modulation is an end result of changes in genetic variants, epigenetic  
13 alterations and gene transcription. Study of an aggressive tumor's proteome has been  
14 instrumental in the identification of targets for therapeutic strategies. Emerging proteomic  
15 techniques have shown potential to characterize the dynamic regulation or dysregulation  
16 of protein expression and function. Cancer proteomic profiling has been used for the  
17 characterization of specific tumors and systematic review of these data using  
18 bioinformatics has provided insight into pathophysiology.

19 Kinase inhibitors have played an important role in the treatment of cancer, thus  
20 we utilized proteomic techniques focusing on phosphorylation events. Our group  
21 assessed iTRAQ phosphoproteome and kinome peptide array profiling in WHO grade II  
22 and III meningiomas (16). This study was validated in a larger cohort of patients and  
23 clearly illustrates how analysis of protein functions and networks can yield unique  
24 signature and targets of potential diagnostic and prognostic value, in well-defined  
25 histological specimens (16).

26 Using a similar experimental design (16), we identified dysregulated proteins and  
27 cascades in clinically aggressive 1.5 meningiomas. While unique and well-defined  
28 signatures were seen across meningioma grades (16), dramatic molecular differences  
29 were not observed between WHO I versus 1.5. These observations were not  
30 unexpected with both having WHO I bland histological features. iTRAQ and peptide chip  
31 identified 32 phosphoproteins and 10 phosphopeptides, respectively. Combined  
32 datasets revealed mechanisms of 1.5 tumors, allowing molecular characterization. AKT  
33 mutation or activation is not a defining feature of this group. The AHR cascade can affect  
34 cellular transduction through interactions with Rb (40).

1 Evidence for Rb1 signaling in the pathogenesis of grade 1.5 meningiomas is as  
2 follows: 1. the kinome revealed a significant increase in Rb1 phosphorylation levels  
3 predicted to occur at the S780 site, 2. the predicted phosphorylation site is a consensus  
4 for CDKs kinases, 3. the canonical pathway analysis identified the cell cycle G1/S  
5 checkpoint signaling and western blot analysis revealed significant related increases in  
6 CDK4, CDK6 and Rb1 S780 (Figure 2e). Rb1 is a commonly affected tumor suppressor  
7 gene in cancers (41), regulating multiple pathways to influence proliferation, migration,  
8 invasion, and cell cycle (42). Identification of hyperphosphorylation on RB\_774\_78  
9 in grade 1.5 meningiomas defined this group. Phosphorylation of many sites on Rb1 by the  
10 cyclins/CDKs has been described (43, 44). Rb1 harbors up to 16 potential S/T-P  
11 consensus sites for CDKs (44). The majority of the phosphosites are clustered at the  
12 carboxyl-terminus. The RB\_774\_786 (I-R-P-P-I-L-S-P-I-P-H-I-P) peptide contains 3  
13 phosphosites: T774, T778, and S780. The sequence of RB\_774\_786 (I-R-P-P-I-L-S-P-  
14 I-P-H-I-P) displays the S/T-P consensus site, which includes T778 and S780. The  
15 consensus analysis predicted S780 as being the most likely to be phosphorylated (score  
16 = 0.926) when compared to T774 and T778 sites (Supplementary Figure S3c). Rb1  
17 S780 has been described (45) while T774 and T778 remain uncharacterized. A  
18 commercially available antibody allowed investigation of S780 hyperphosphorylation.  
19 Our results demonstrate that inactivation of Rb1/EF2 signaling can distinguish the  
20 subgroup of 1.5 meningioma from WHO I. The kinome profiling suggested mTOR  
21 phosphorylation (FRAP\_2443\_2455) is upregulated in 1.5 meningiomas (Fig 1c,  
22 Supplementary Table S7). The literature reports that Rb1 pathway inactivation results in  
23 mTOR overexpression (46). mTOR may directly regulate AKT phosphorylation, by  
24 decreasing AKT S473 (Fig 4a) aiding mTORC1 upregulation (47) (Fig 4). While our data  
25 reveal a decrease in both AKT S473 and T308 and no change in RPS6KB1 T389, the  
26 relationship to mTOR is unsettled (Figure 2a). This will be the focus of future work. The  
27 increase in Rb1 S780 phosphorylation may be driven by CDK4/6 overexpression (Figure  
28 2e and Figure 4) which results in the dissociation of E2F-1, allowing E2F-1 to activate  
29 the transcription of genes required for DNA synthesis and cell cycle progression (45).

30 Phosphorylation of Rb1 S780 proved to be a real time biomarker for identifying  
31 the 1.5 meningiomas. Hyperphosphorylation of Rb1 S780 correlated with increased  
32 recurrence/progression in a comprehensive cohort of patients. This was not the case in  
33 WHO grade I, II or III tumors, illustrating the specificity for grade 1.5 meningiomas.

1 While all grade I tumors, in the discovery set, were first time surgery samples, 3/5  
2 of the grade 1.5 tumors were initial surgical samples. None of the discovery set samples  
3 had been treated with radiation prior to surgery. To understand if Rb1 S780 is predictive  
4 we organized a TMA cohort of samples including WHO grade I, 1.5, II and III  
5 meningiomas. Samples were from initial and subsequent (2<sup>nd</sup>-5<sup>th</sup> operations)  
6 interventions and sometimes before or after radiation treatments. RB1 S780 staining  
7 was specific for the grade 1.5 group of meningiomas. Patterns for high Rb1 S780  
8 staining: at the 1<sup>st</sup> surgery, or 2<sup>nd</sup> through 5<sup>th</sup> remained high. This suggests that Rb1  
9 S780 is phosphorylated at an early stage when WHO grade I histology is reflected,  
10 predicting the clinical activity seen with these aggressive tumors. Rb1 staining did not  
11 have this predictive ability in post-radiation cases. Rb1 dephosphorylation upon radiation  
12 treatment occurs (34) and may be involved with meningioma escape from treatment. It is  
13 very interesting that the levels of RB1 S780 staining are also decreased (to levels seen  
14 in WHO grade I tumors) in the more aggressive WHO grade II and III tumors, before and  
15 after radiation. This likely reflects the complexity and heterogeneous nature of  
16 meningiomas, deeper than the WHO grading scheme. The potential for therapeutic  
17 targeting of the RB1 pathway may lead to better outcomes for this particular subset of  
18 grade 1.5 tumors. To this end, the *in vitro* characterization of the Rb S780 site is under  
19 investigation.

20 Other authors have identified this group of histologically benign meningioma with  
21 clinically aggressive behavior (3, 4, 5, 6, 8, 12). So far, proposed molecular grading  
22 schemes for 1.5 meningioma have been based mainly on cytogenetics. The  
23 identification of chromosomal abnormalities (12, 6) with potential prognostic value have  
24 been reported in histologically benign meningiomas. A recent study shed light onto  
25 several meningioma subgroups defined by genomic methylation status (13). Compared  
26 with WHO grading, classification by individual and combined methylation classes more  
27 accurately identifies patients at high risk of disease progression in tumors with WHO I  
28 histology (13). While mutational analysis and genome methylation are promising, our  
29 data demonstrate the potential of Rb1 S780 staining for the diagnosis of 1.5  
30 meningiomas and a marker for recurrence. Non-irradiated grade 1.5 samples had  
31 significant hyperphosphorylation at RB1 S780, versus WHO I. In resequencing NF2,  
32 SMO, AKT, KLF4 and TRAF7 we found that mutations did not correlate with RB1 S780  
33 staining. While there may be trends for TRAF7 and KLF4 mutations in benign and  
34 aggressive courses, respectively, these alterations did not identify grade 1.5

1 meningiomas. Mechanisms driving the clinical phenotype and oncogenesis of  
2 meningiomas are very complicated. Prognostic biomarkers and treatments are likely to  
3 draw from genetic, transcriptional, epigenetic and proteomic mechanisms. The time has  
4 come for meningioma pathologic specimens to be analyzed with several biomarkers for  
5 the most accurate identification and prediction of clinical course. This will result in the  
6 best outcomes for meningioma patients.

7       Taken together, these data provide a basis for the concept that Rb1 S780  
8 phosphorylation may play a role in the progression/recurrence phenotype in grade 1.5  
9 meningiomas, and suggest it may be a potential predictive biomarker. Staining of Rb1  
10 S780 is a promising biomarker for risk stratification, diagnosis, and should be validated  
11 in a larger prospective cohort.

## 1 **Figure Legends**

2 **Figure 1: Kinome profiling (STK PamChip®) of grade 1.5 meningioma. a:** STK  
3 PamChip® peptide chip array experimental design and workflow. Grey circle is the  
4 theoretical epitope. **b:** Heat map of peptide signal intensities. The bar on the top right  
5 shows the relation between 2Log transformed signal intensities and color. Red:  
6 hyperphosphorylation. Green: hypophosphorylation. (+) highest phosphorylation levels,  
7 (-) lowest phosphorylation levels. Each row represents clustered peptides detected on  
8 the STK PamChip® with 2Log signal intensity above the limit of detection (101). Each  
9 column represents a group of pooled samples submitted to the kinome profiling (grade I  
10 and 1.5). **c:** Fold change analysis (cut-off 20% and p-value<0.05) reveals 10  
11 hyperphosphorylated peptides. RED: upregulation, GREEN: downregulation. The order  
12 of phosphorylated peptides is according to fold changes, from largest to smallest. The  
13 grey row indicates RB1 chosen for further validation. **d:** The IPA core analysis of  
14 hyperphosphorylated peptides in meningioma grade 1.5 predicts activation of Fcγ  
15 Receptor-mediated Phagocytosis in Macrophages and Monocytes, Endothelin-1, Type II  
16 Diabetes Mellitus, and Glioma signaling pathways. The x-axis shows  $-\log(p\text{-value})$ . The  
17 numerical value on the top represents the percentage of genes in the dataset. Numerical  
18 values on the right show the number of genes in the canonical pathway.

19  
20 **Figure 2: Western Blotting validation of aggressiveness-related canonical**  
21 **pathways and kinases in grade 1.5 meningioma.** Western Blotting assay was  
22 performed in three grade I and three grade 1.5 fresh-frozen tissue lysates. Cropped  
23 lanes. **a:** PI3K/AKT/MTOR targets. **b:** ERK-MAPK targets. **c:** cAMP/PKA targets. **d:**  
24 CDC42-RAC1-RHOA targets. **e:** cell cycle G1/S checkpoint targets. **e:** The table  
25 demonstrates a list of significantly altered proteins and kinases in 1.5 meningiomas as  
26 well as their respective p-values. Bold letter and ‘ \* ’ indicate proteins and kinases with p  
27 < 0.05. See also Supplementary Figure S7 for band intensity and statistics.

28  
29 **Figure 3: RB1 S780 validation in a TMA cohort of clinical specimens. a:**  
30 Representative WHO I and 1.5 meningioma H&E section from two cases. **b:** The same  
31 representative cases stained with Rb1 S780. Note the increased cytoplasmic and  
32 nuclear staining in the 1.5 meningioma. **c:** Ratio of Rb1 S780 staining per total tissue  
33 area versus tumor grade – all samples (non-irradiated samples + samples with prior  
34 radiation). **d:** Ratio of Rb1 S780 staining per total tissue area versus tumor grade – non-  
35 irradiated samples only. **e:** Ratio of Rb1 S780 staining per total tissue area versus tumor  
36 grade (only samples with prior radiation). In **c**, **d**, and **e**, x-axis indicates Rb1 S780  
37 intensity of staining. Y-axis shows meningioma grades. “n” indicates number of samples.  
38 Statistical significance by mixed-effects regression using grade ranks to test for an  
39 ordinal relationship. See also Table 3a and 3b. **f:** Progression/recurrence-free survival  
40 versus ratio of Rb1 S780 staining per total tissue area independently of tumor grade – all  
41 samples. **g:** Progression/recurrence-free survival versus ratio of Rb1 S780 staining per  
42 total tissue area independent of tumor grade in non-irradiated samples. **h:**  
43 Progression/recurrence-free survival in irradiated tumors, ratio of Rb1 S780 staining per  
44 total tissue area independent of tumor grade. **i:** Progression/recurrence-free survival in  
45 all histologically benign meningiomas (grades I: n=47, and 1.5: n=44). **j:**  
46 Progression/recurrence-free survival in all non-irradiated histologically benign  
47 meningiomas (grades I: n=47, and 1.5: n=28). **k:** Progression/recurrence-free survival in  
48 all irradiated histologically benign meningiomas (grades I: n=0, and 1.5: n=16). **l:**  
49 Progression/recurrence-free survival in non-irradiated histologically benign  
50 meningiomas. Grade I tumors were samples collected at the first and only surgery

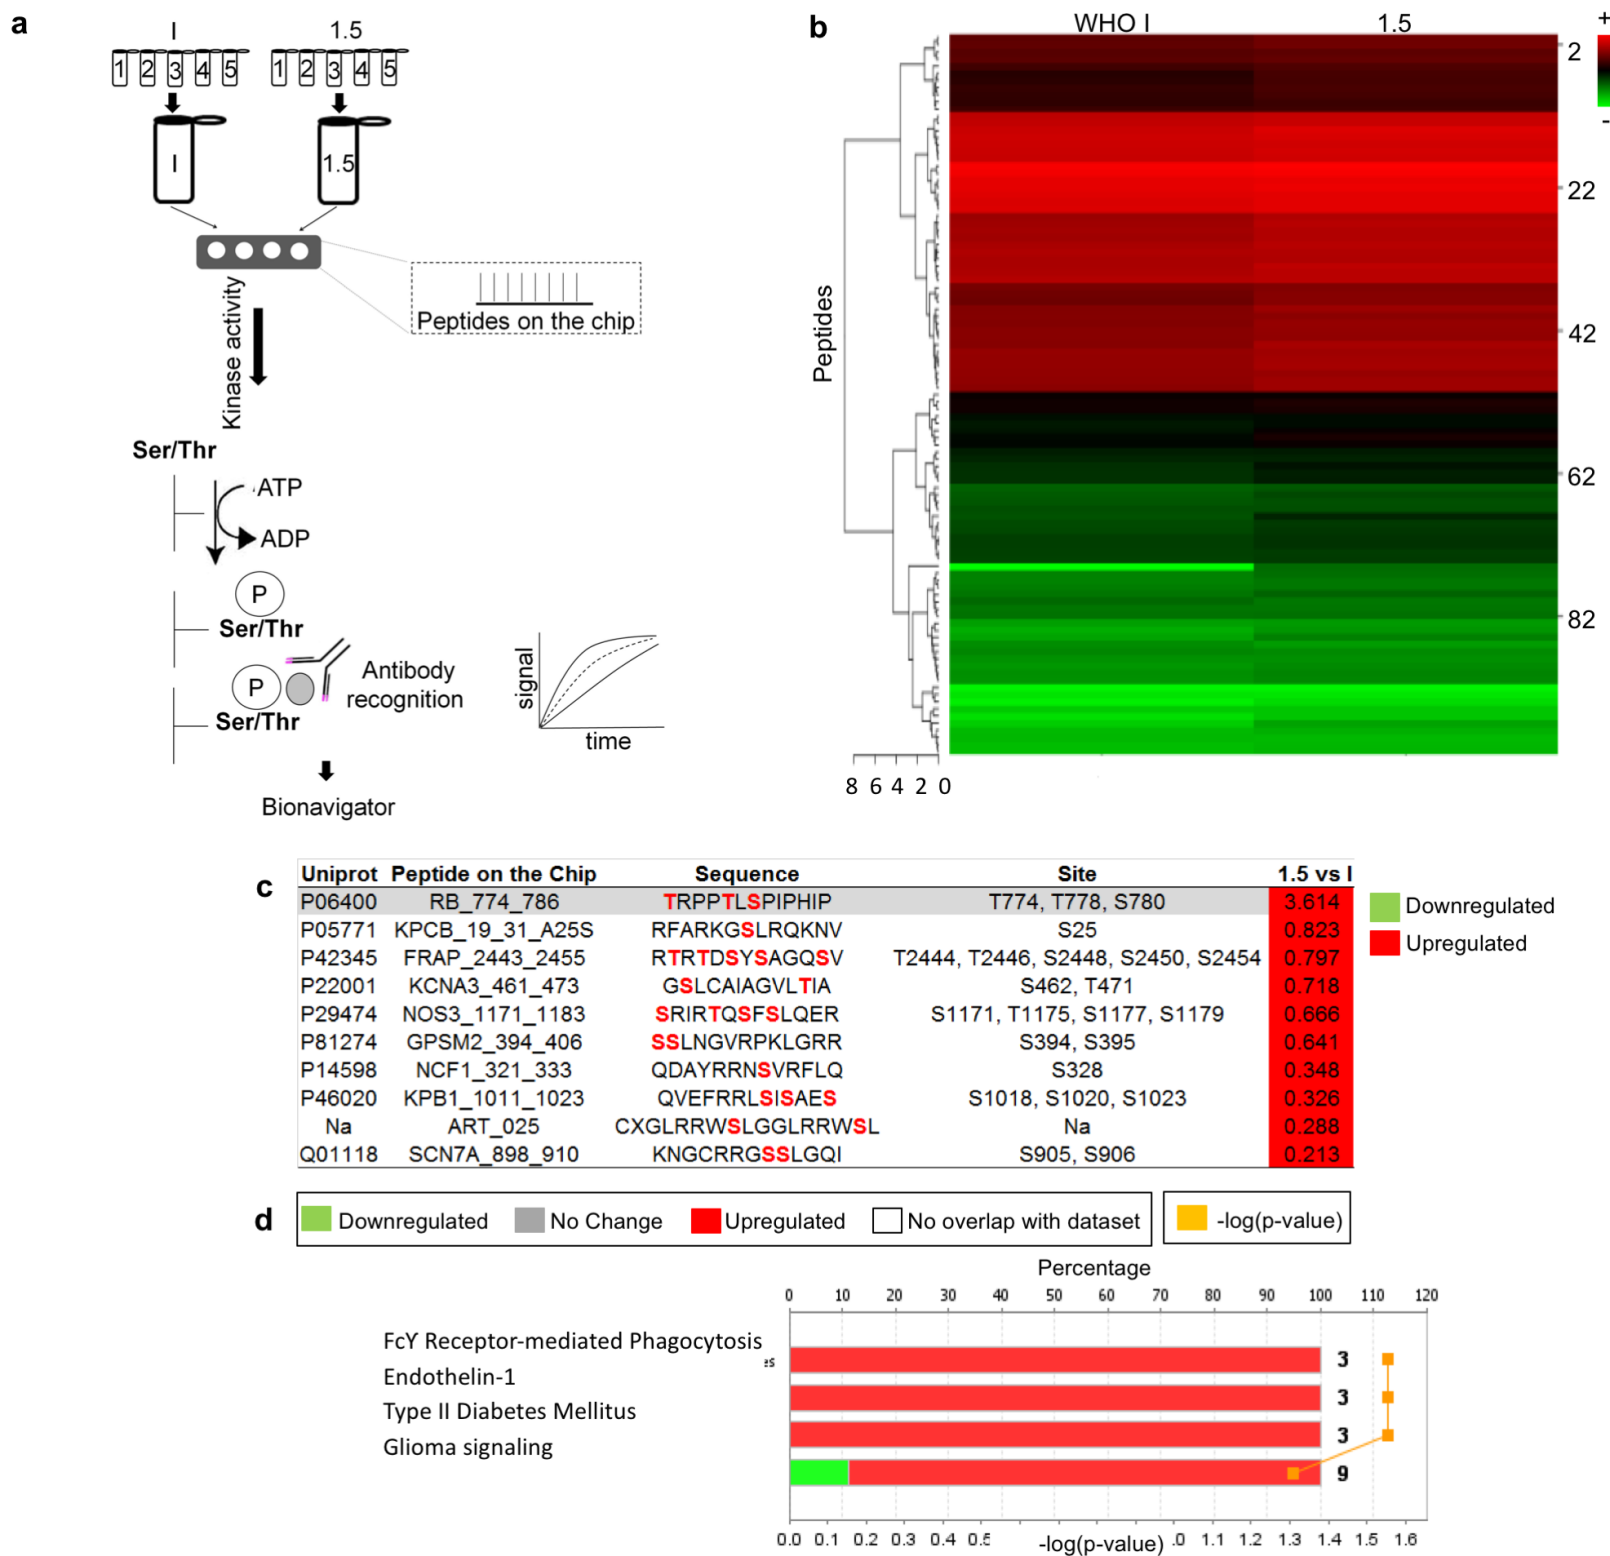

1 (n=47). Grade 1.5 tumors were collected from either initial (1<sup>st</sup> surgery, n=16) or  
2 recurrent (2<sup>nd</sup>-5<sup>th</sup> surgery, n=12) specimens. **m**: Progression/recurrence-free survival of  
3 grade II and III tumor patients –non-irradiated samples (n=32). Statistical significance by  
4 Cox regression. See also Table 3a and 3b.

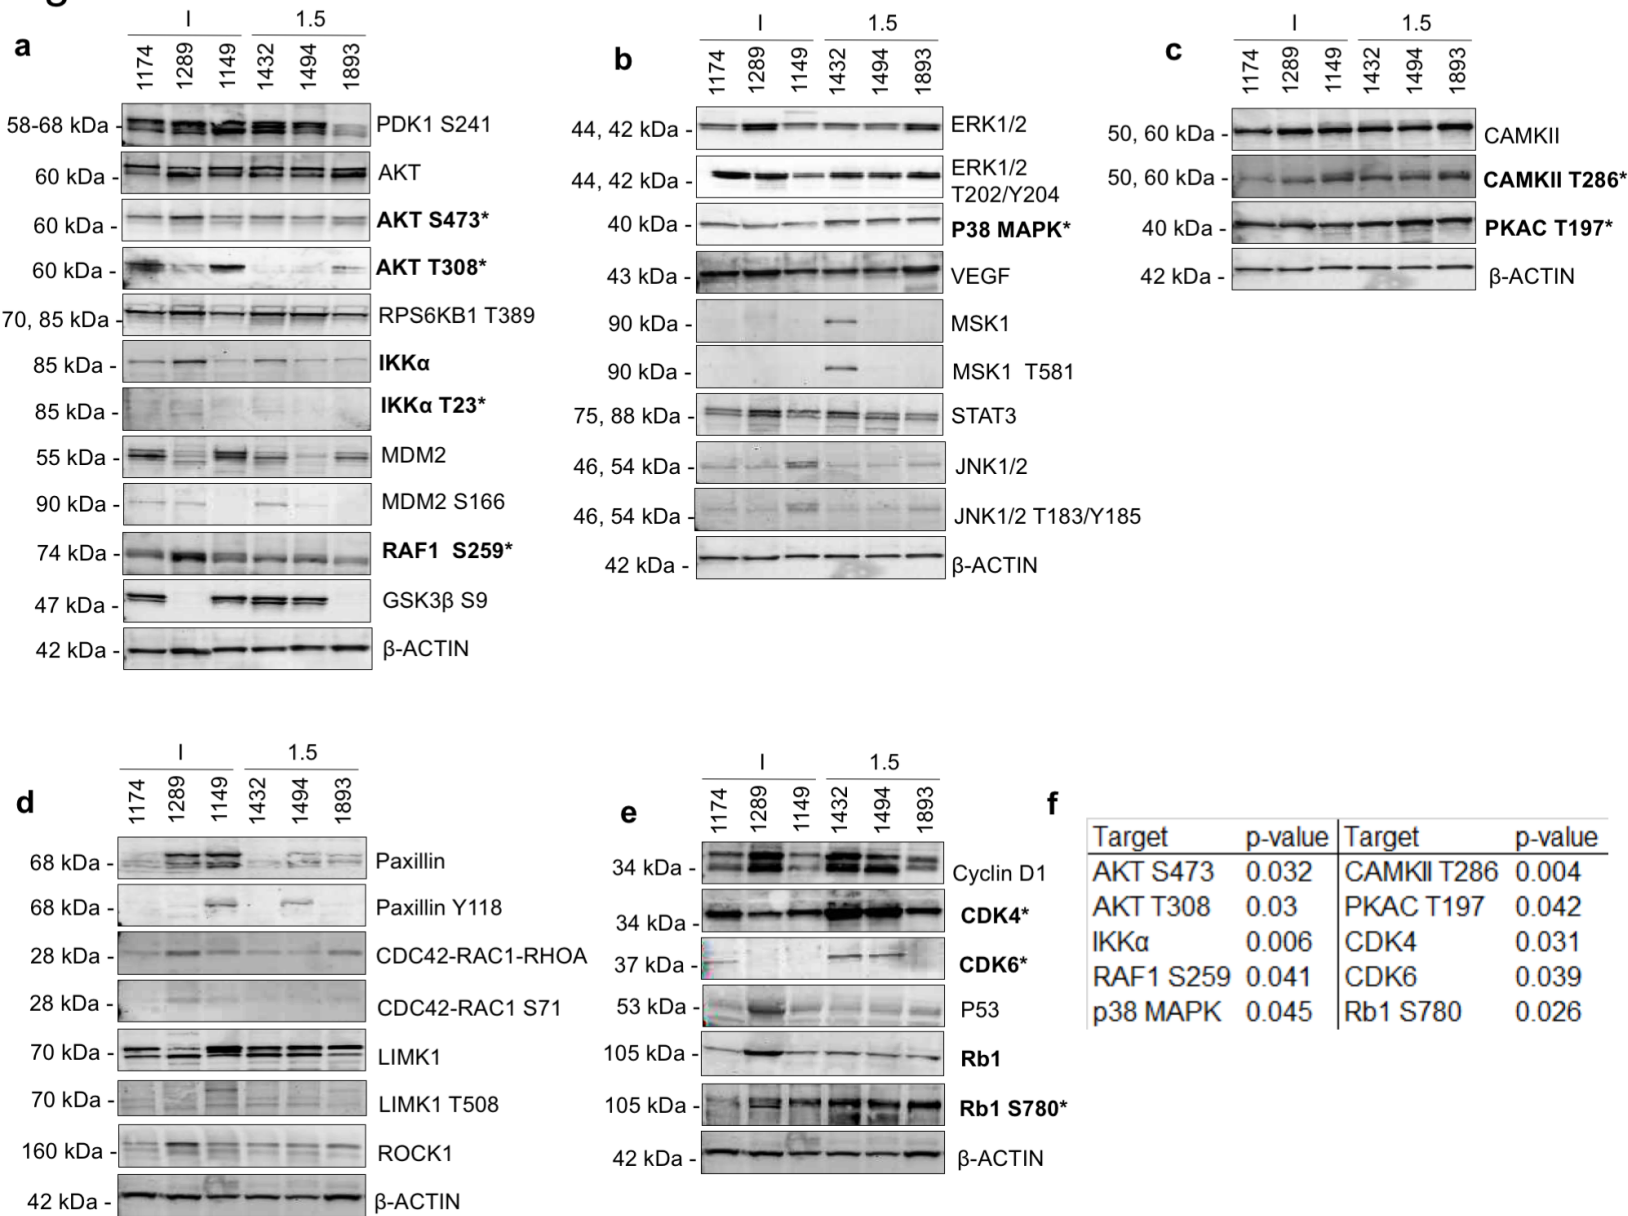

5  
6 **Figure 4: Proposed meningioma grade 1.5 mechanism of aggressiveness:** Gene  
7 names are shown at the approximate positions where their encoded proteins function in  
8 the pathway. Colored molecules were significantly altered. Grey molecules: affected with  
9 no significant changes in regulation. Red molecules: significant upregulation. Green  
10 molecules: significant downregulation. Continuous arrows: activation. Dashed arrows:  
11 inactivation.
